1 INTRODUCTION

1.1 Problem Definition

There are 5 processes ,one of them parent process and others are children processes.Parent process reads $(2^n) \times (2^n)$ character from two input files.Each character is converted to ASCII code integer equivalent.These $(2^n) \times (2^n)$ characters are elements of square matrix.So after reading two files,there are 2 square matrix A and B. Parent process P1 receives this two square matrices.After it creates 4 children process.Tasks of children processes are calculating one quarter of multiplication matrix of matrix A and matrix B.Each children process calculates one quarter of multiplication matrix,then gives result to parent.After all quarters are calculated,parent process combines them and calculates the singular values of multiplication matrix.

To achive this tasks,there must created bi-directional pipes between parent process and each of its children.And also parent process P1 must catch the SIGCHLD signal and perform a synchronous wait for each of its children.And in case of CTRL-C, all 5 processes must exit gracefully.

2 METHOD

2.1 Problem Solution

For solving this problem,firstly,I read $(2^n) \times (2^n)$ characters from each input files.After reading files, I convert each read character to ascii integer equivalent.After I create two matrices that are matrix A and matrix B.Then I divide matrices into arrays for quarters of matrix multiplication. I save up half and down half of matrix A into arrays.Then I also save left half and right half of matrix B into another arrays.I create bi-directional pipes between every child and parent.For example: A bidirectional pipe between P1 and P2, a bi-directional pipe between P1 and P3, and so on.Then I create 4 children process by fork system call.After, I write up half of matrix A and left half of matrix B in write-end of pipe of parent for children process P2 ; then, up half of matrix A and right half of matrix B in write-end of pipe of parent for children process P3; then , down half of matrix A and left half of matrix B in write-end of pipe of parent for children process P4 and down half of matrix A and right half of matrix B in write-end of pipe of parent for children process P5.In each children process,I calculate one quarter of matrix multiplication of matrix A and matrix B.Each children write own results in bi-directional pipes. While these are doing,parent process P1 catch the SIGCHLD signal and perform a synchronous wait for each of its children. P1 blocks its execution until all of its children have completed their calculations. This is a synchronization barrier and I apply this in my program.After all children have completed their calculations,parent process P1 read each outputs from bi-directional pipes and forms multiplication matrix C.And finally,parent process P1 calculates all singular values of C and prints them on screen.

Functions that I use in my code for solving problem:

char* readForP1(char* inputFile,int n) : This function reads $(2^n) \times (2^n)$ character from given input files.

int * convertAsciiInt(char *buffer,int bytes): This function converts each read character to ASCII code integer equivalent.

ssize_t readFile(int fd, void *buffer, size_t byteCount): This function reads given byte character from given file according to file descriptor.

int convert2D(int array[],int row,int column,int startPoint):** This function converts 1D array to 2D array.

int* divide(int* total,int size,char pos): This function divides given matrix into 4 part.

int ** multiplication(int matrix1,int row1,int column1,int** matrix2,int column2):** This function makes matrix multiplication of given 2 matrix.

int createProductMatrix(int r,int first[][r],int second[][r],int third[][r],int fourth[][r]):** This function forms a matrix from given 4 quarter of it.

void sigChildHandler(int sigNo): SIGCHLD signal handler.

void sigIntHandler(int sigNo): SIGINT signal handler.

I create fork for children processes and bi-directional pipes in main function.

NOTE: Below functions that I use in my code for calculating singular value calculation stage. For this stage I use ,from "Numerical Recipes in C" (Cambridge Univ. Press) by W.H. Press, S.A. Teukolsky, W.T. Vetterling, and B.P. Flannery resource that is in link:
<http://cacs.usc.edu/education/phys516/src/TB/svdcmp.c>

void svdcmp(double **a, int m, int n, double w[], double **v);

double pythag(double a, double b);

void free_dvector(double *v, int nl, int nh);

double *dvector(int nl, int nh);

double **dmatrix(int nrl, int nrh, int ncl, int nch);

3 RUNNING RESULTS:
